Abstract

The results of studies of the foam concrete on activated water of mixing with the use of two types of foaming agent are demonstrated. It has been shown that activation of the mixing water increases the multiplicity and foam stability. The use of activated with the electromagnetic field and electric current water of mixing enhances strength characteristics and reduce shrinkage deformation of composites. The increase of water resistance of foam concretes prepared on activated water of mixing compared with control compositions it was established. The comparative characteristic of foam concrete on the two types of foaming agent is given.

1. Main text

Among the large variety of modern building materials used in construction, significant amounts fall on foam and aerated concrete. These materials are widely used in the construction of buildings and structures, in heat-insulating products. In recent years, the production of foam concrete has outpaced the use of aerated concrete. Due to the toughening of the thermal engineering standards for heat-insulating materials, it is important to improve the physical, mechanical and operational properties of foam concrete. Many authors have established that the quality management of concretes and other composite materials is possible with different impacts on both non-hardened and hard materials and on its components. At the same time, acoustic, magnetic, electrical, mechanical, laser and other effects are used largely [1-5].

Water is a required component for cement composites and water determines their technological properties. In our previous studies, we investigated the effect of electrochemical and electromagnetic activation (using electric current and the electromagnetic field to get changes in the physical and chemical properties of water) and proved the improvement of the physical and mechanical properties of cement stone and heavy concrete due to the use of activated mixing water [6, 7]. In this paper, we present studies of the production technology and physical and mechanical properties of foam concrete with the use of electrochemically and electromagnetically activated mixing water. From the results given below it follows that such mixing water activation in foam concrete gives an even greater effect. It is known that the formation of foam concrete with the optimal structure is possible under the condition of a combination of numerous physico-technical and physicochemical factors: the viability of the foam film, composition, density and other properties of the foam concrete.

The hydrodynamic effect is one of the factors determining the viability of the foam film. According to the theory of structural and mechanical stability of foams, the stability of adsorption layers is determined both by surface forces
and by mechanical properties of foamed films [8]. If there is some way to improve these properties, it will increase the stability of foam. It is the provision of a structural-mechanical stability factor that can give the foam the greatest stability. Below we present studies of the effect of activated water, both on the foam properties and on the properties of foam concrete.

The ability of surfactants to form micelles to a significant extent depends on the length of hydrocarbon radical [8]. Their sizes depends on the concentration above which micelles form (the critical micellization concentration, CMC) [9]. There are many methods for determining CMC. All of them are based on a sharp change in the physicochemical properties of surfactant solutions in the transition from a molecular solution to a micellar solution.

Thus, the creation of a foam and mixtures of foam concrete with stable structure possible with the use of activated water and aqueous solutions for mixing.

2. Description of the conceptual design

To study aqueous solutions of foaming agents, foam, cement stone and foam concrete, we used the following components: we took portland cement CEM I 42.5 B as a binder (GOST 31108-2003); as foaming agents: “Esapon 1850” - non-ionic surfactant, which is a saturated fatty alcohol with ethylene oxide, and "Arekom-4" (TU 2481-007-11084661-2003) - foaming agent, which is an aqueous solution of anionic surfactants and auxiliary additives; as a solvent, we used water that meets the requirements of GOST 23732-79.

We carried out the activation of water and aqueous solutions using the unit for the anti-scale treatment of water systems UPOVS2-5.0 by "Maxmir" [10]. We conducted experimental research in accordance with the operation modes of the apparatus. In total, we used nine modes, the cipher of which is composed of alphanumeric characters. The letter designation E + M means that the natural water or its solution has been subjected to joint successive activation by an electric current (electrochemical activation) and an electromagnetic field in the working gaps of the apparatus. The digital designation corresponds to the selected mode of operation of the device, which characterizes the current strength (switch position) in the cell circuit and the winding of the magnetizing coils. The modes and their parameters are presented in table 1.

We used a stalagmometric method to study the indicator of the critical micelle concentration of Arekom-4. The surface tension values of the solutions are shown in Table 2. The critical concentration of Arekom-4 foaming agent was calculated for each type of water according to the curves of the surface tension versus the concentration of the foaming agent. The values of the CMC are given in Table 2.

Based on the tabulated values of the surface tension of the solutions, we constructed the graphical dependencies shown in Fig. 1.

We can see that the curves of the dependence of the surface tension on the concentration of the foaming agent for some types of activated water (1-3, 3-3 and 6-3) differ slightly from the other curves. However, there is no sharp difference between them.

From the results of studies it follows that the critical concentration of foaming agent Arekom-4 is in the range 0.2 ... 0.3%.

Various properties of the foam influence on the structure formation and hardening of the foam mass, they affect the subsequent performance of buildings constructed from foam concrete.

To assess the quality of foaming of the solutions and the prepared foams we have investigated the multiplicity and stability of foam.

We determined the foam multiplicity of Arekom-4 and Esapon 1812 foaming agents in accordance with TU 2481-007-11084661-2003.

As a solvent for foaming agents, we used non-activated water and water activated according to the regimens given in Table 1.
Test results for the determination of the foam multiplicity for Arekom-4 and Esapon 1812 foaming agents with the use of activated water are shown in Fig. 2.

1) non-activated water; 2) water activated according to the ‘1-1’; 3) water activated according to the ‘1-3’; 4) water activated according to the ‘1-6’; 5) water activated according to the ‘3-1’; 6) water activated according to the ‘3-3’; 7) water activated according to the ‘3-6’; 8) water activated according to the ‘6-1’; 9) water activated according to the ‘6-3’; 10) water activated according to the ‘6-6’

---

**Fig. 3.** Change of the foam stability for Arekom-4 (■) and Esapon 1812 (□) on the mode of water activation:
1) non-activated water; 2) water activated according to the ‘1-1’; 3) water activated according to the ‘1-3’; 4) water activated according to the ‘1-6’; 5) water activated according to the ‘3-1’; 6) water activated according to the ‘3-3’; 7) water activated according to the ‘3-6’; 8) water activated according to the ‘6-1’; 9) water activated according to the ‘6-3’; 10) water activated according to the ‘6-6’
It follows from the figure that with increasing current in the conductor of magnetizing coils and in the working gap of the electrodes, the multiplicity of the foam increases.

We determined the stability of the foam in accordance with TU 2481-007-11084661-2003. The results of tests for determining foam stability of foaming agent Arekom-4 and Esapon 1812 using activated water are shown in Fig. 3.

It follows from the figure that with increasing current in the conductor of magnetizing coils and in the working gap of the electrodes, the stability of the foam increases with the use of both types of foaming agents.

Obtaining an effective insulating material with low density (less than 500 kg/m³) and low thermal conductivity remains one of the main tasks in the production of foam concrete. For its implementation, it is necessary to pay special attention to the technology of manufacturing this material, in particular, to the choice of the foaming agent type, the selection of the water-hard ratio, and the quality of the cement. Modification of the mixing water will have a definite effect on the material properties of cellular structure.

We examined the foam concrete on 2 types of foaming agent: Arekom-4 and Esapon 1812. We present the results of the dependence of the foam concrete strength on the water activation mode in Fig. 4.

![Fig. 4. Dependence of the change in compressive strength of foam concrete with the foaming agent Arekom-4 (a) and Esapon 1812 (b) on the type of activated mixing water: 1 - water not activated; 2 - the same, processed by a magnetic field; 3 - the same, treated by electric current; 4 - the same, treated by the combined action of an electric current and a magnetic field](image)

We can see from the figure that the use of activated mixing water promotes an increase in the strength characteristics of composites. The water treated by the combined action of electric current and magnetic field makes it possible to increase the compressive strength of foam concrete on the Arekom-4 up to 90%, and on the Esapon 1812 – up to 18%.

Shrinkage is an important property of foam concrete. Shrinkage of foam concrete during drying should not exceed 3 mm/m (for non-autoclave technology materials according to the requirements of GOST 25485-89). Otherwise, the shrinkage strain will cause cracking. This is especially observed in the case of manufacturing large-size products, which include wall structure and slab coverings. According to practical experience of foam concrete application, the width of crack opening in similar products can reach 3...5 mm.

When performing research, the shrinkage was determined on samples in the form of prisms of size 4×4×16 cm. Deformations were measured by dial indicators. Study results of the foam concrete shrinkage (samples were composed with the use of two types of foaming agents and activated mixing water) are shown in Fig. 5.

![Fig. 5. Study results of the foam concrete shrinkage](image)
properties. This phenomenon is also associated with the development of moisture shrinkage. In the presence of moisture, the material swells, and when dried, it shrinks. Emerging stresses (due to changes in humidity) loosen the structure of the material and reduce its strength. Humidity deformations, in the first place, depend on the ratio of gel-like and crystalline phases in the cement stone. The resistance of the material increases in such conditions with increasing crystalline phase. In this case, it is important to increase the strength of the structural mesh from the hardened cement stone in the porous system. Previous studies (6, 7) showed that mixing cement with activated water, contributes to a significant increase in strength of cement stone. It was found that with the same degree of hydration and porosity, the strength of the cement stone depends on the nature of the hydrates crystallization. The high strength of cement stone was noted in the compositions with the optimal combination of weakly crystallized hydrates with dense sections of the crystallized structure. Weakly crystallized hydrosilicates are apparently a binder cementing unreacted clinker grains, as well as crystals of calcium hydroxide and ettringite hydroxide. The density of the material significantly affects the water resistance of the cement compositions, in addition to the above factors. One of the main factors affecting the density, regardless of the initial water-cement ratio, is the form of water-solid interface. Water, as known, is one of the main elements that form the structure of cement stone; water is involved in the formation of hydrate compounds and the formation of pores.

Studies of the water resistance of foam concrete were carried out on samples measuring 4 × 4 × 16 cm. The test results of samples after 3 days of incubation in the environment shown in Fig. 6.

Fig. 5. Dependence of foam concrete shrinkage with foaming agents "Esapon 1812" (a) and "Arekom-4" (b) on the activation mode of mixing water: 1) water not activated; 2) water activated by the E + M mode (1-1); 3) the same, E + M (3-3); 4) the same, E + M (6-6)

Fig. 6. Dependence of the softening coefficient of foam concrete on the mixing water activation mode: 1) water, not activated; 2) water activated by the E + M mode (1-1); 3) the same, E + M (3-3); 4) the same, E + M (6-6)
Studies show an increase in the water resistance of foam concrete prepared on activated mixing water, compared with the control compositions on average by 10%.
